DESCRIPTORS	*Disadvantaged Groups; Eating Habits; Low Income Groups; *National Surveys; *Nutrition; Population Trends; *Surveys

ABSTRACT

This report of the Department of Health, Education, and Welfare to the Congress concerns the nutrition of people living in 10 states, from 1968-70. The data presented in this booklet present the preliminary findings for New York City and New York State. The data represent selected characteristics and findings in the population groups that were studied. The intent of the surveys was to determine the nutrition levels of disadvantaged families rather than provide a true picture of a cross section of the total population. Sampling selection was based on 1970 census data, although the actual survey was instituted in June 1968 and not concluded until May 1970. Because of the incomplete nature of the data forming the basis of this report, it is considered that one should be cautious in drawing conclusions. Characteristics of the population sampled (education, age, income, ethnic group) and biochemistries as well as anthropometry (height and weight) and diet are the kinds of information presented. (Author/JW)

TEN-STATE NUTRITION SURVEY IN THE UNITED STATES, 1968-1970

Preliminary Report to the Congress
April 1971

U.S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE

Table of Contents

I. INTRODUCTION

The data on which this report is based were collected between 1968 and 1970.

The following tables present the preliminary findings from this Ten-State Nutrition Survey. The data represent selected characteristics and findings in the population groups that were studied. The intent of the surveys was to determine the nutrition levels of disadvantaged families rather than provide a true picture of a cross section of the total population. Sampling selection was based on 1960 census data although the actual survey was instituted in June 1968 and not concluded until May 1970.

Editing of the data is continuing at the Center for Disease Control and, upon completion of the data edit and analysis, a final report will be presented to this Committee. Because of the incomplete nature of the data forming the basis of this report, one should be cautious in drawing conclusions. It must also be emphasized that the judgments for interpretation of biochemical measurements presented are based on guidelines establishing "deficient" and "low" levels. While these are widely used standards, there is not a precise relationship between these evidences of malnutrition and occurrence of clinical abnormalities.

II. CHARACTERISTICS OF SAMPLE POPULATION

The numbers of households and individuals providing the basis of this report are presented in Table 1. Though these households and individuals do not represent all those who will be included in the final edited report, it is clear that there were sufficient losses of households and individuals in all localities so that the data to be presented in the later tables should not be extrapolated to other segments of the population.

Four out of the many biochemical variables that were studied were selected for inclusion in this report. A summary of the numbers of these test results available for each survey is shown in Table 2.

The individuals who were examined on each survey did not differ substantially from those who refused examination or who were not available for examination. Tables 3-6 present a comparison of selected demographic characteristics of the examined and non-examined individuals in each survey. Insofar as differences are present which suggest a bias in the interpretation of the final data, we plan to make further detailed tabulations to investigate the degree of this bias. Examples of these problem areas are seen in the over 60 age group in California where there were twice as many individuals over 60 in the not examined group, as compared to the examined group. In South Carolina there were three times as many white individuals in the not examined group (Table 5) as compared to the examined group. This is also seen when one looks at the percentage of individuals examined who were below the poverty level in the various states. Comparison of individuals at similar economic levels may be made between the states though there is little justification for making overall comparisons between the various surveys as the average economic status of the individuals in the different surveys differ considerably (Table 7). The indication of the economic status used in these surveys is the Poverty-Index Ratio (Orshansky Index). This is a composite index based on income, family size, farm or non-farm, and sex and age of head of household. For purposes of this report the poverty line is set at a Poverty-Index Ratio of 1.00.

1. Participation of Households and Individuals in Nutrition Surveys by State and New York City, 1968-1970 (Preliminary)

State	Total Number of Households in Sample	Total Number of Households Interviewed	Percent of Households Interviewed	Number of Households with Members Attending Clinic	Percent of Interviewed Households with Members Attending Clinic	Total Number of Individuals in Interviewed Households	Number of Individuals from Interviewed Households Attending Clinic	Percent Attending Clinic of Total Individuals in Interviewed Households
Total	29612	23192	78	12649	55	83597	38501	46
Texas	1990	1782	90	1183	67	7806	4215	54

III. BIOCHEMISTRY

A. HEMOGLOBIN

The measurement of the amount of hemoglobin in blood is one way of assessing the status of iron nutriture in individuals. The data regarding hemoglobin levels in the populations surveyed are presented in Tables 8A–8E. The levels of hemoglobin used in determining deficient and low levels are presented in Table 8A. The cutoff level for "deficient" is set in such a way that most authorities would accept these values as abnormal; the cutoff level for "low" is open to more variation in interpretation and generally represents a borderline situation.

It is clear from Tables 8A and 8B that in all areas individuals living below the poverty level have greater problems of iron nutriture than individuals living above the poverty level. Again, one should be very careful, however, in comparing percentages from state to state because of the widely different percentage of individuals examined who are in the poverty group.

In Table 8C the data suggest that males as a group have a higher % of deficiency than females. These differences may be due to the use of inappropriate standards for males and will be revised if further consultation and investigation reveal the need for such a revision.

It is evident from Table 8D that the group at greatest risk for having a high prevalence of probable iron-deficiency anemia are children under the age of 6. It is also clear from these data that the elderly segment of the populations studied are also at high risk in this regard.

In all states the minority groups in the populations surveyed have a substantially higher prevalence of abnormal hemoglobin levels than the white populations.

A review of these data on hemoglobin levels suggests that possible iron-deficiency anemia is a major problem in most segments of the populations surveyed. Any measures designed to alleviate this problem should be directed at all segments of our population with emphasis on the poor, the minority groups among us, children, and elderly individuals. Figures 1a—1f graphically portray the findings presented in Tables 8A—8E.

B. VITAMIN A

The material on plasma vitamin A levels is presented in Tables 9A—9E. In evaluating these data one should bear in mind that the examinations were performed during different seasons in different areas. The inconsistencies that appear between states may relate to seasonal availability of food sources of vitamin A and may not, therefore, represent real deficiencies.

The data for New York State are not presented because of reporting difficulties which will be corrected prior to the preparation of final reports.

A similar relationship between poverty and evidence of possible vitamin A undernutrition is seen as with hemoglobin. These differences are not as clear cut as with hemoglobin and suggest that the relationship between vitamin A nutrition and socio-economic status is not as strong as between iron nutrition and socio-economic status. This fact should be taken into account in the development of program activities directed towards the improvement of vitamin A nutrition.

There does not appear to be any consistent differences in vitamin A levels between males and females (Table 9C). Data in Table 9D show that the problems of vitamin A nutrition are probably greater in children under the age of 10 as compared to individuals over age 10.

It appears from the data in Table 9E that minority groups have more evidence of vitamin A undernutrition than do white.

These data on vitamin A levels suggest the presence of nutritional problems related to vitamin A intake in minority groups and children under the age of 10. There are no data available from the survey at the present time as to the physiological significance of these low vitamin A levels.

C. VITAMIN C

The data on serum vitamin C levels are presented in Tables 10A—10E. As was seen in data previously presented, the prevalence of potentially abnormal values is greater in the below poverty groups as compared to the groups living above poverty. The data suggest that there is little relationship between age and vitamin C levels (Table 10D). There is some suggestion that minority groups may have more of a problem than whites (Table 10E).

34

Insofar as serum vitamin C levels are a reflection of dietary intake of vitamin C, there does not seem to be a major problem with vitamin C nutriture in the population groups surveyed except among the poor whites and Negroes in Kentucky, West Virginia, Texas, and Louisiana.

D. RIBOFLAVIN

Tables 11A—11E present data for urinary riboflavin excretion as measured in casual urine samples. Individuals living below the poverty line generally had a higher prevalence of values below standard than those living above poverty. Children had more deficient and low values than subjects in older age groups. As previously noted for the other biochemical values reported, minority group individuals had more values in the deficient and low range than the whites. The significance of these deficient and low values is presently unknown.

E. COMBINED BIOCHEMICAL VALUES

Tables 12A—12F present biochemical findings combining data of persons having at least two measurements that were deficient or low out of the set of determinations for hemoglobin, vitamin A, vitamin C, and riboflavin. Overall, only 0.2 percent of subjects were in the deficient category on two or more of these measurements while 4.2 percent were deficient or low on two or more. Kentucky and South Carolina had the highest percentage of subjects with two or more deficient or low values. Those individuals living at poverty or near poverty levels had a higher prevalence of two or more abnormalities than those living above the poverty level. Comparisons by sex show no marked differences; the ethnic group comparisons show consistently more low or deficient results for the Negro groups in all the populations surveyed.

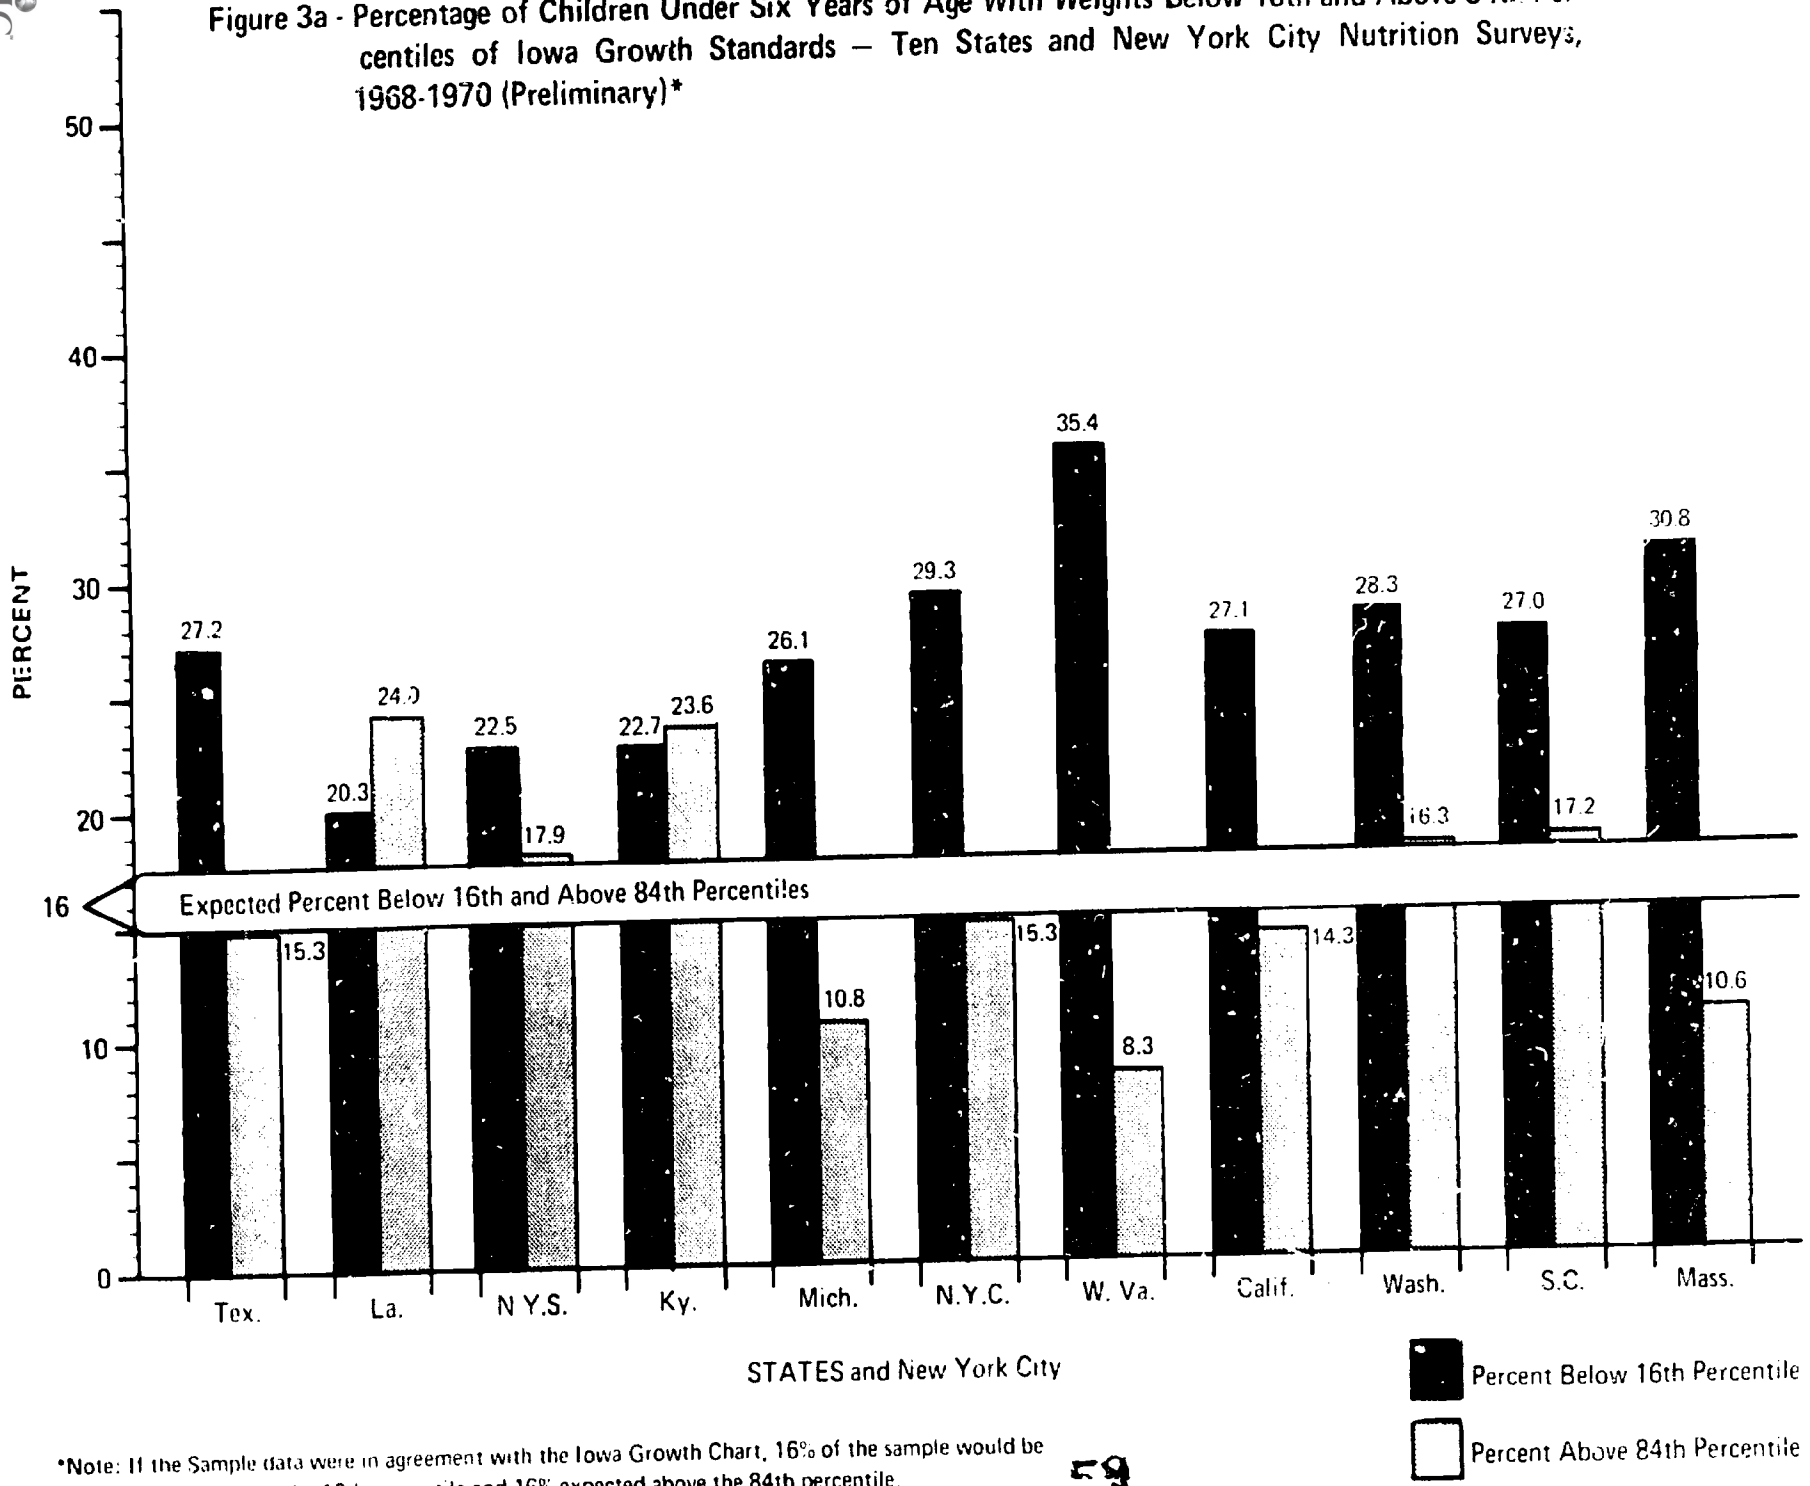
IV. ANTHROPOMETRY

Numerous body dimensions were measured on persons selected for clinical examinations but this presentation gives only height and weight data for preschool children (figures 3a—3f). Comparisons are with the Iowa Growth Charts, standards based primarily on children attending Iowa preschool and school programs in the 1930's. These charts are in wide current use, as arbitrary standards, by physicians in the United States.

Figures 3a and 3b show (for weights and heights respectively) the overall percentages of children in each survey who were below the 16th percentile and above the 84th percentile of the Iowa standard. Figures 3c and 3d, for weights and heights, show the percentages of children below the 16th percentile of the standard, according to whether they are living below or above the poverty line. Figures 3e and 3f show the same comparison for white and Negro children.

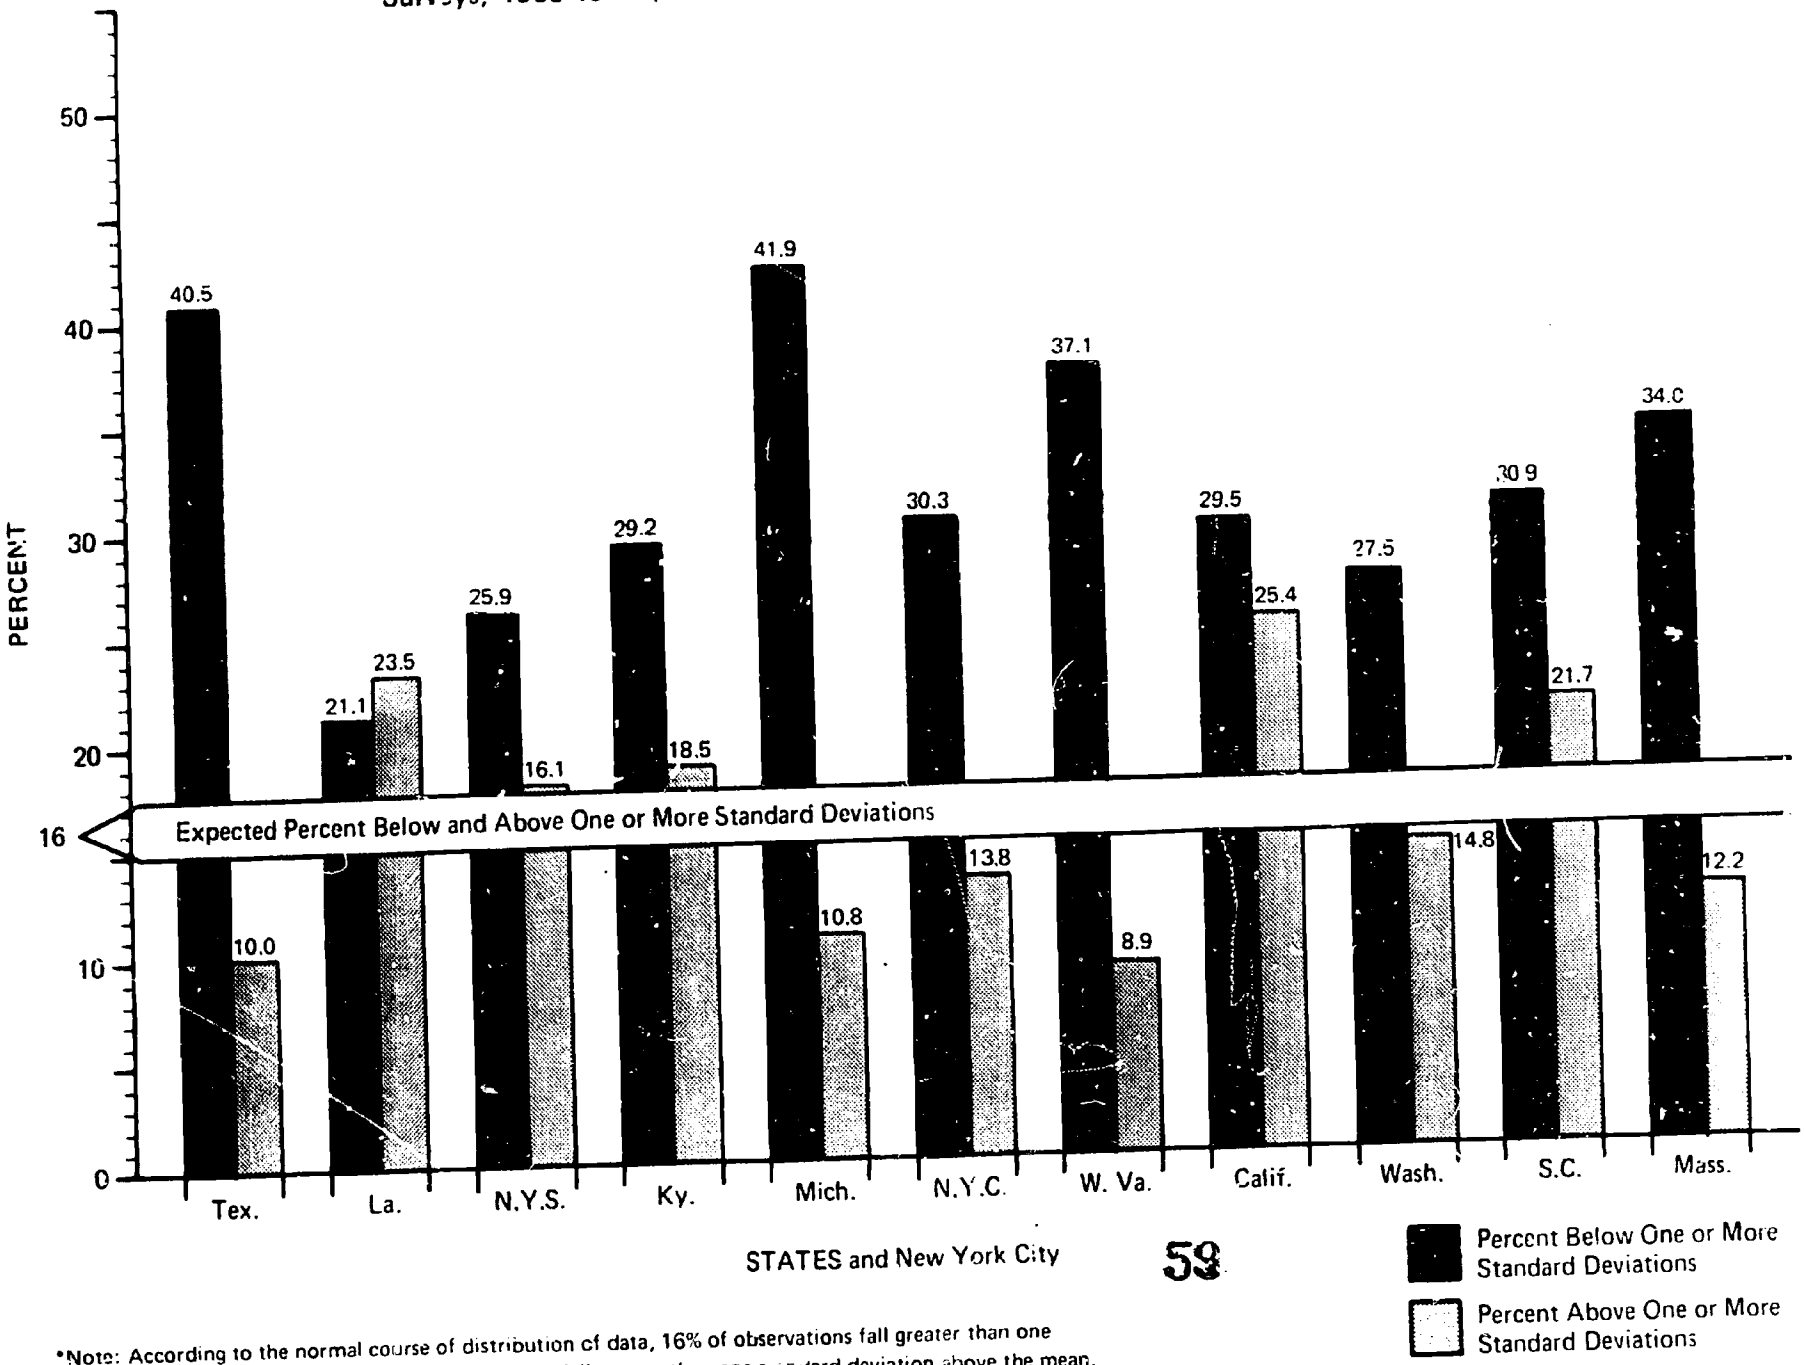
For all the surveys the results generally show an excess of low heights and weights compared to the Iowa standard. Weights tend to be less deviant than heights, indicating children somewhat "behind" but slightly "chunkier for their height" than the standard. In several states an excess of high values were also found, indicating greater variability than obtained among the children who made up the standard; this has been found in several recent surveys by others. The general pattern was a greater percentage of low measurements for children living below the poverty line than for those living above the poverty line. Ethnic group differences were distinct in several states but occurred in both directions. For all these findings, investigation of other measurements made such as thickness of skinfolds and measurements at ages over 6 years, may further help to explain these differences.

Figure 3a - Percentage of Children Under Six Years of Age With Weights Below 16th and Above 84th Percentiles of Iowa Growth Standards — Ten States and New York City Nutrition Surveys, 1968-1970 (Preliminary)*



*Note: If the Sample data were in agreement with the Iowa Growth Chart, 16% of the sample would be expected below the 16th percentile and 16% expected above the 84th percentile.

Figure 3b · Percentage of Children Under Six Years of Age With Heights One or More Standard Deviations Below and Above Mean of Iowa Growth Standards — Ten States and New York City Nutrition Surveys, 1968-1970 (Preliminary)*



*Note: According to the normal course of distribution of data, 16% of observations fall greater than one standard deviation below the mean, and 16% fall greater than one standard deviation above the mean.

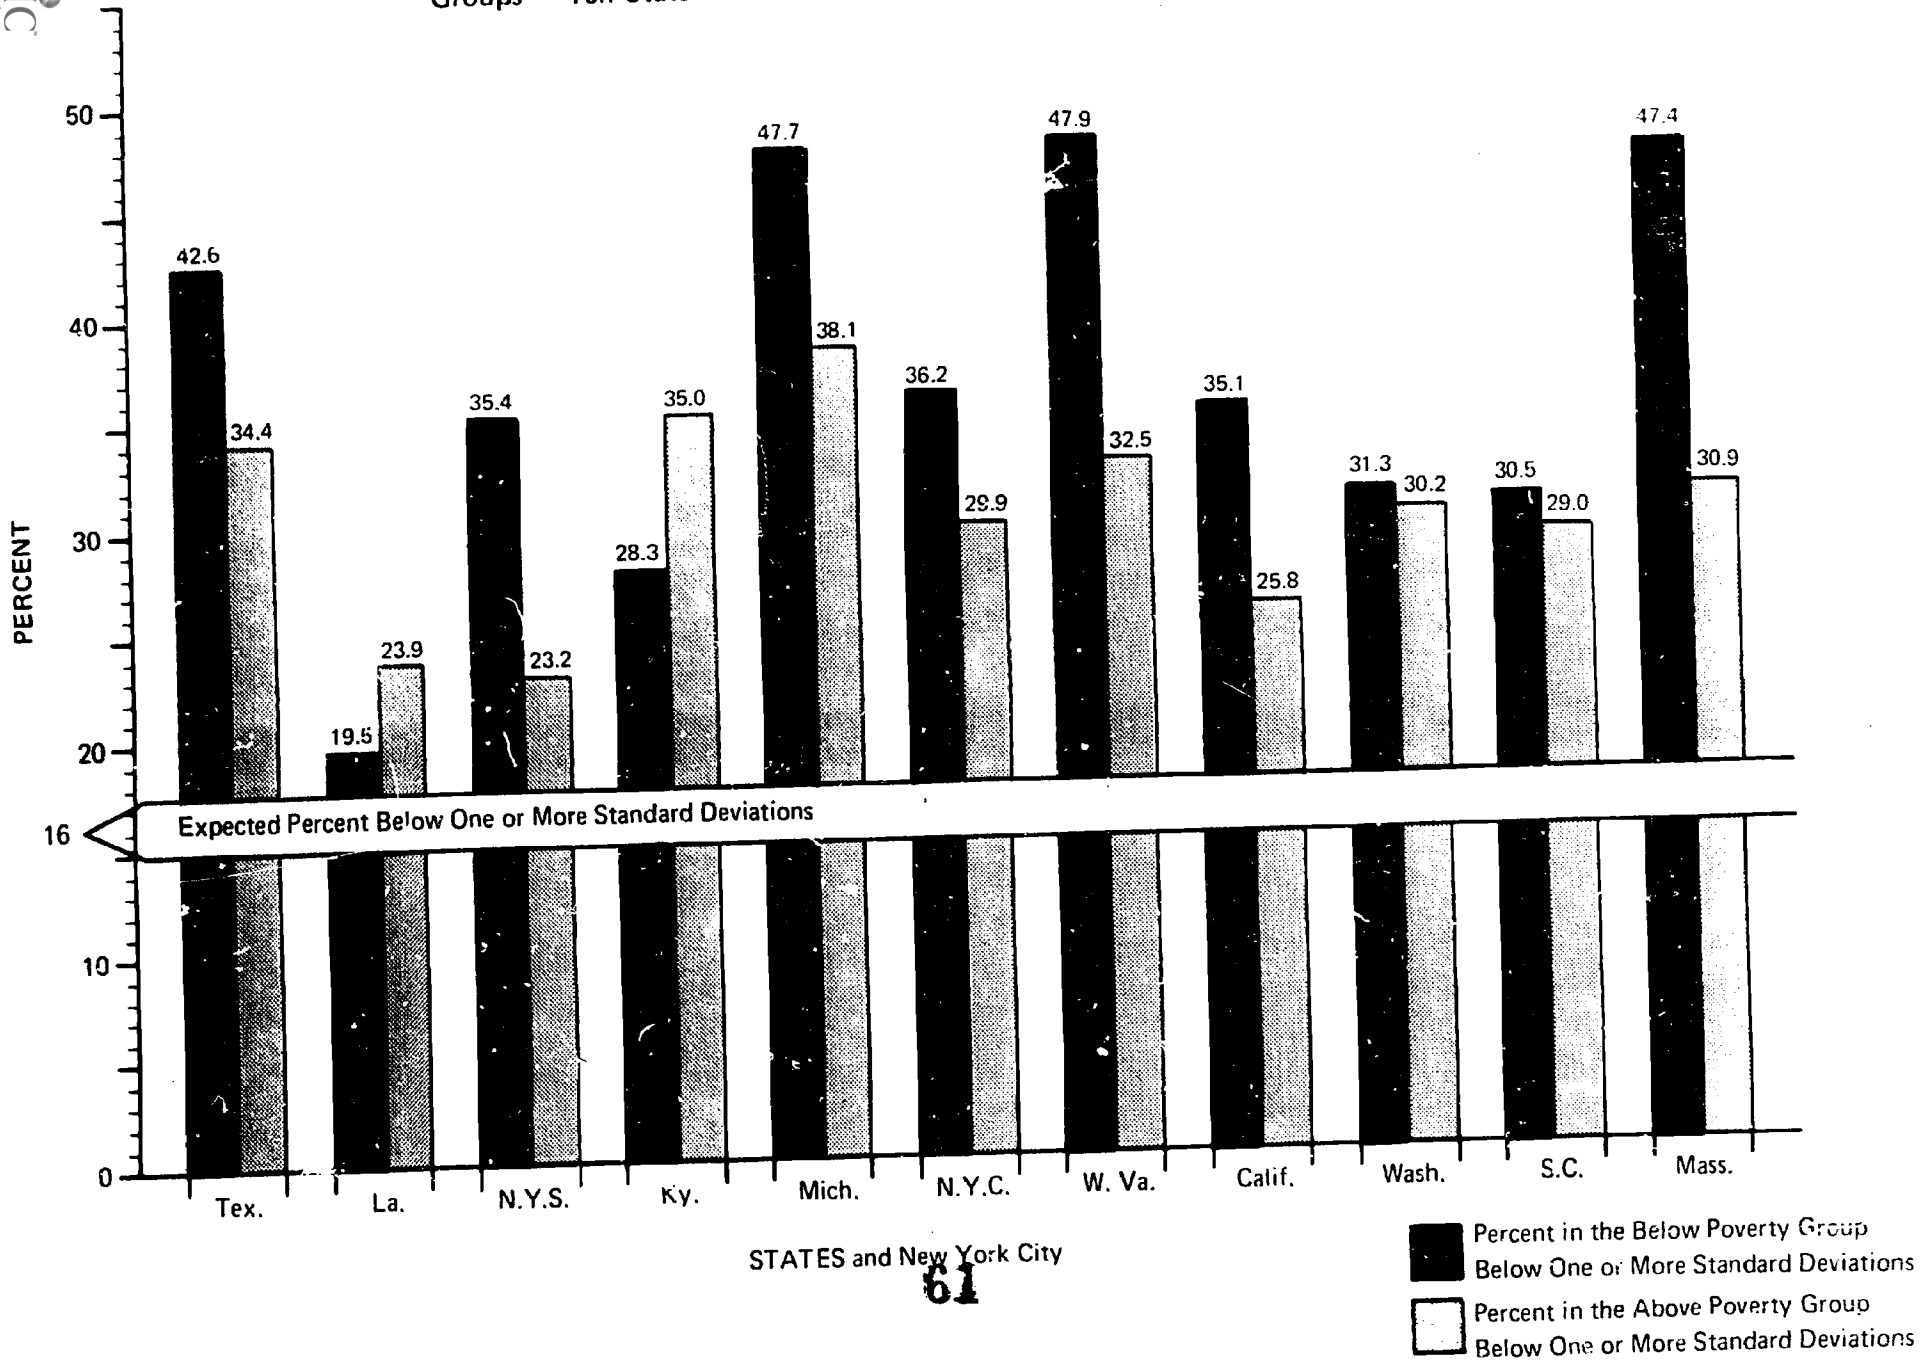

Figure 3e - Percentage of White and Negro Children Under Six Years of Age With Weights Below 16th Percentile of Iowa Growth Standards — Ten States and New York City Nutrition Surveys, 1968-1970 (Preliminary)

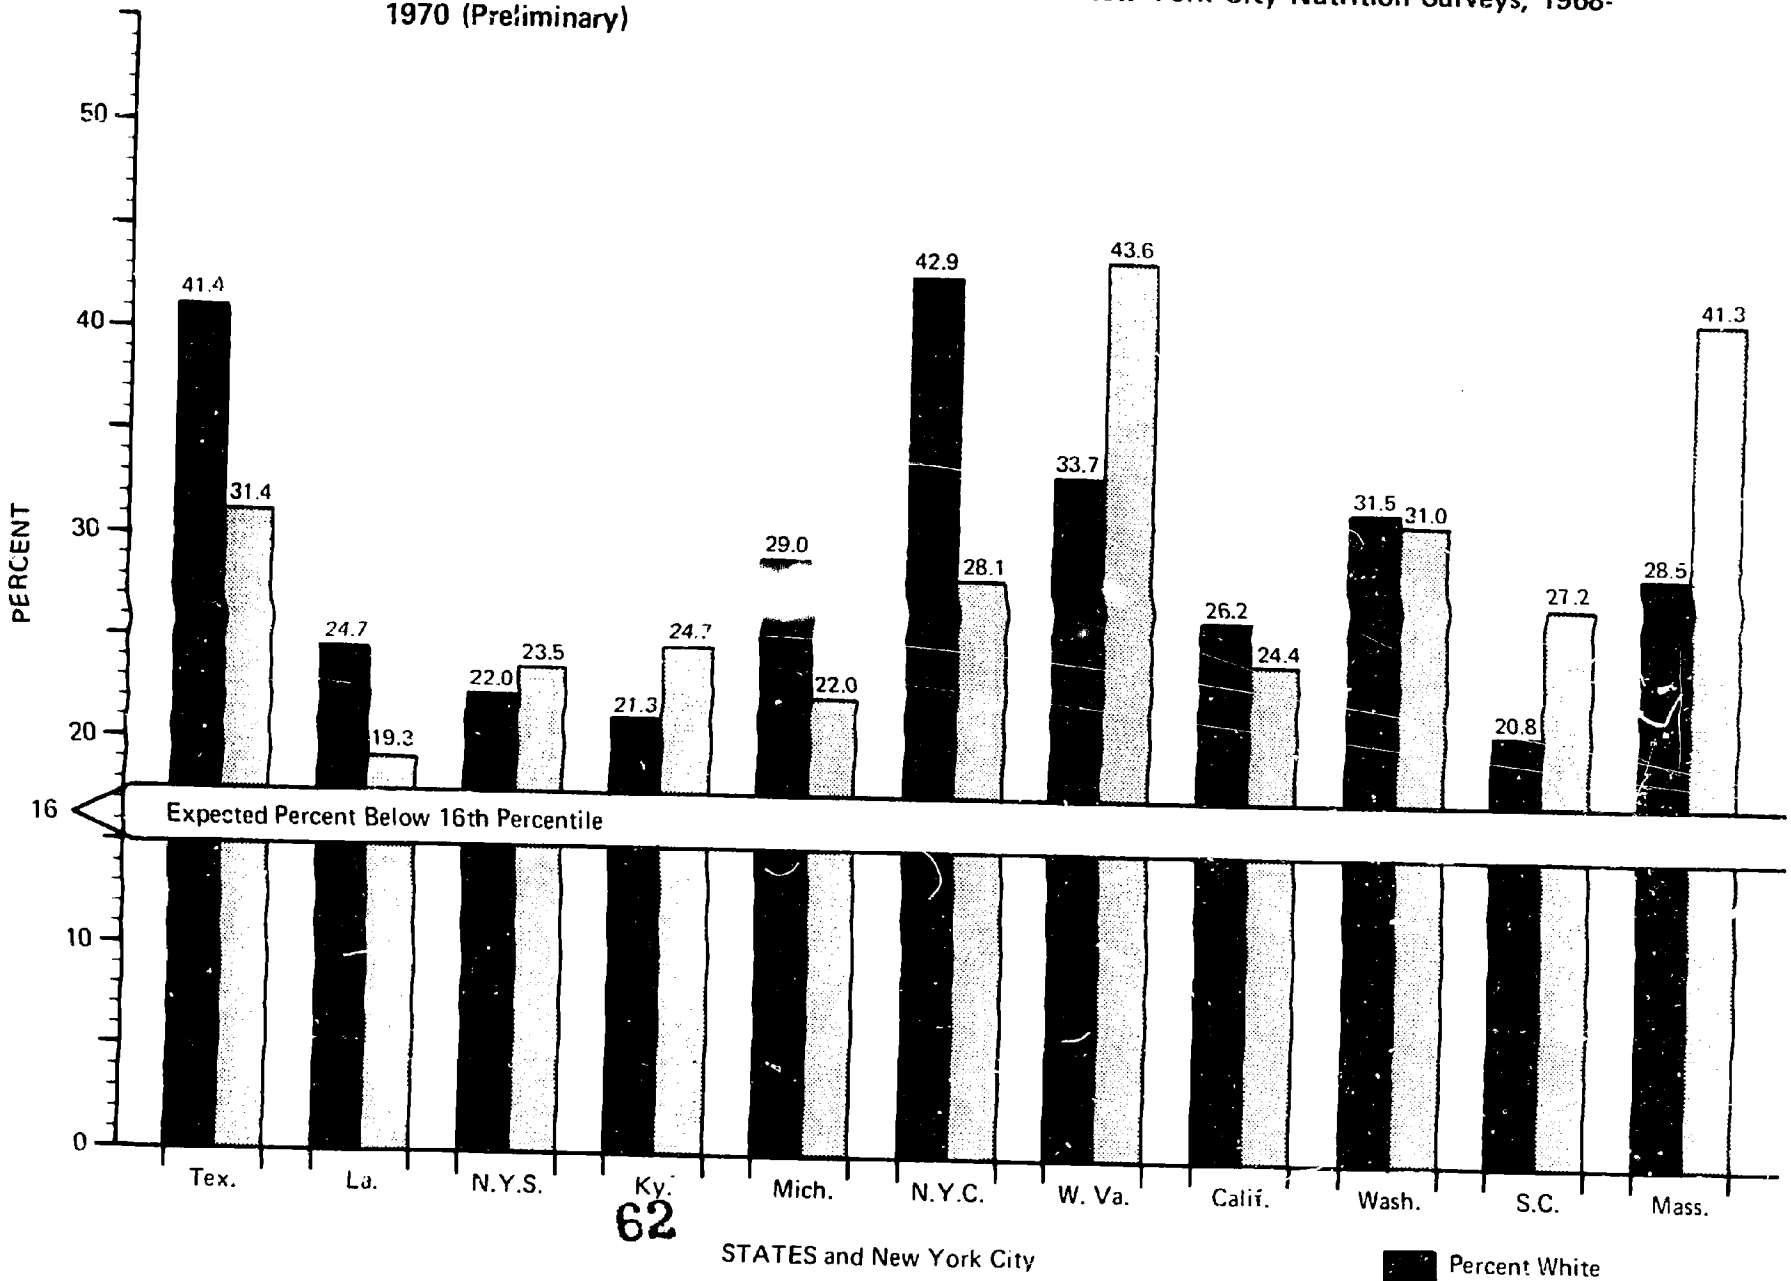

Figure 3f - Percentage of White and Negro Children Under Six Years of Age With Heights One or More Standard Deviations Below Mean of Iowa Growth Standards – Ten States and New York City Nutrition Surveys, 1968-1970 (Preliminary)

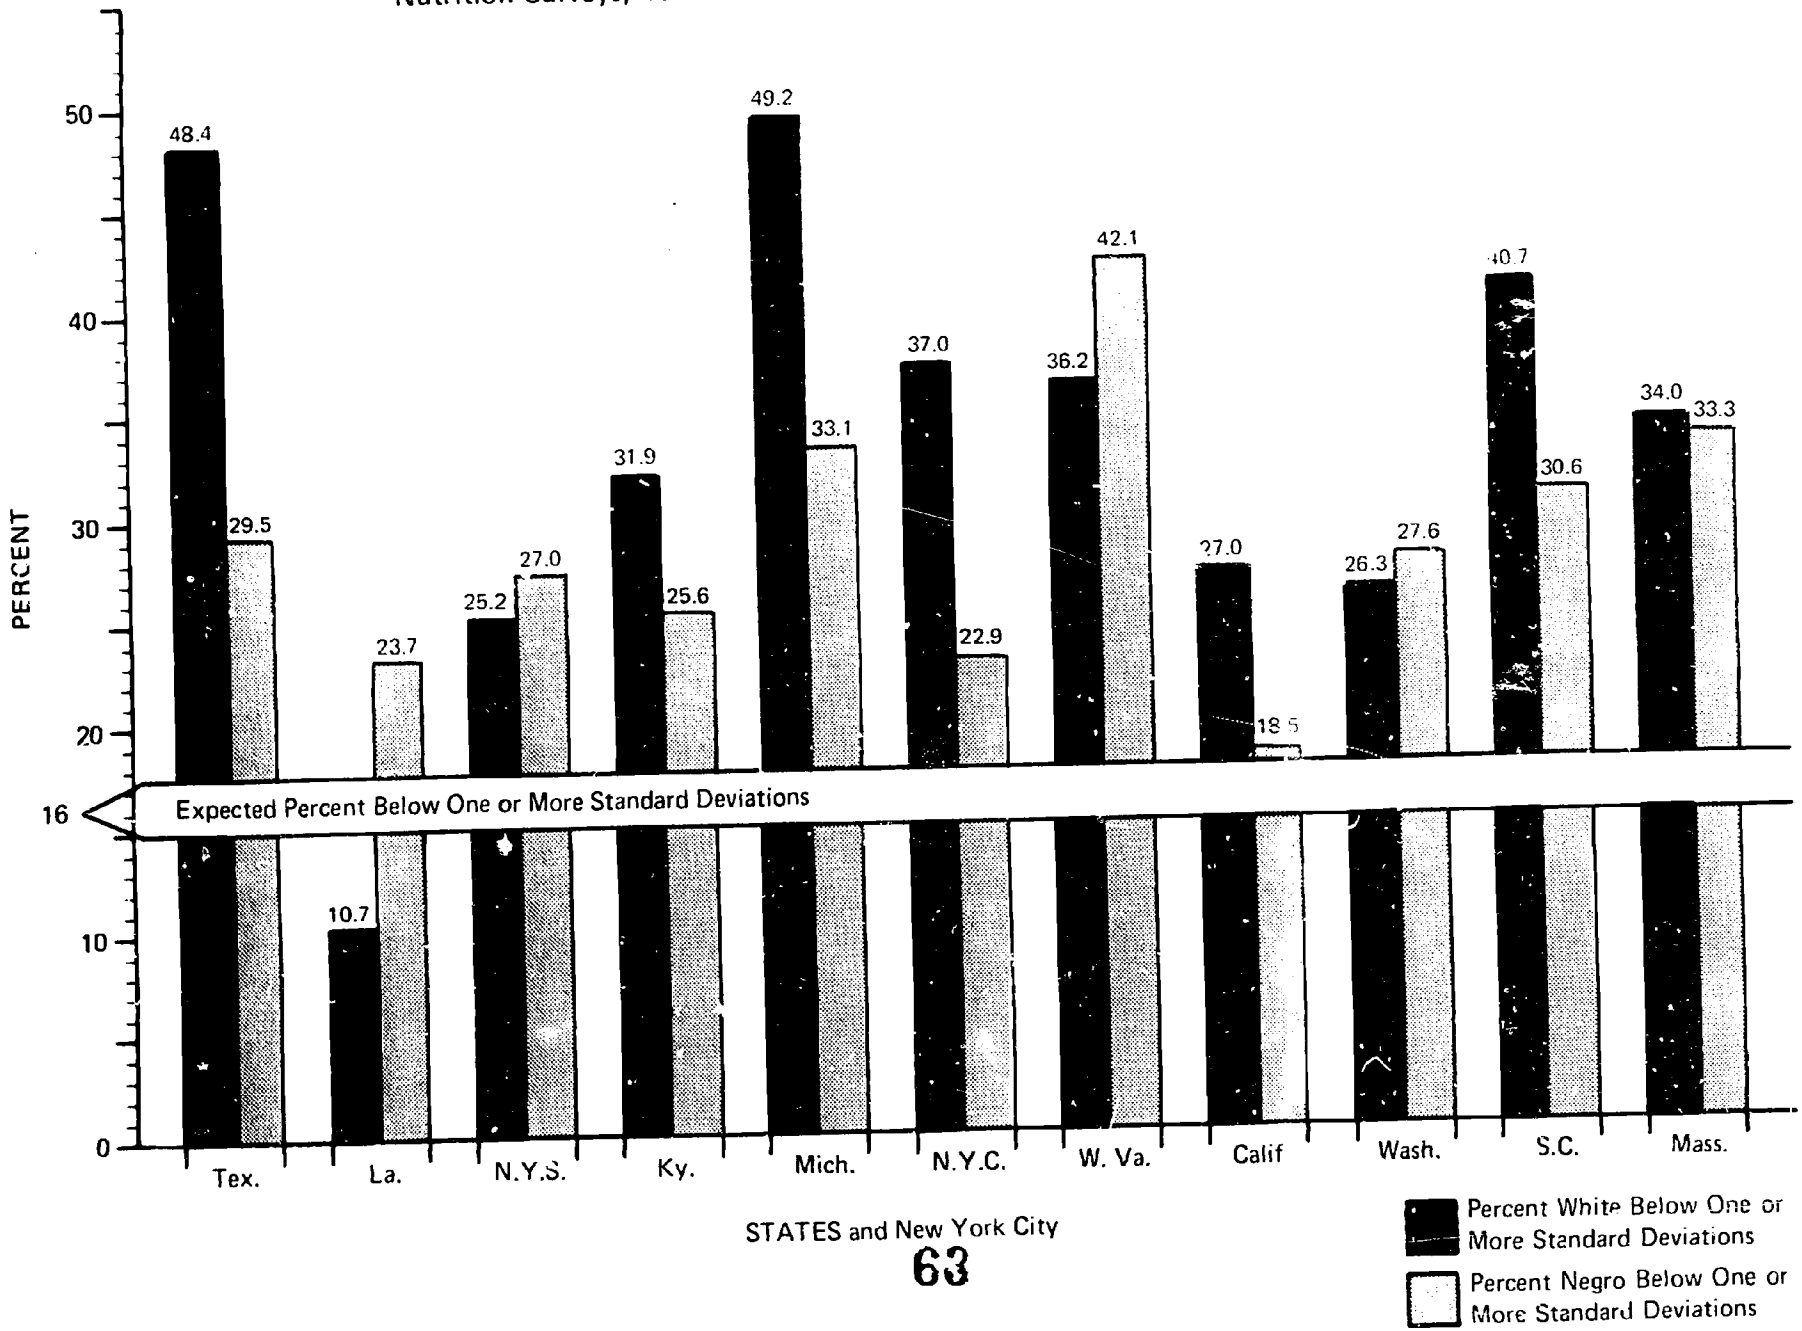

V. DIETARY

Dietary intake of selected nutrients as a percentage of reference standards is presented in Tables 13A—13E for groups of individuals living below or above the poverty level. There was no consistent pattern of influence seen between socio-economic status and dietary adequacy.

In most population groups studied, the percentage of individuals having adequate caloric intakes was similar in the below and above poverty groups. Exceptions were among the elderly in Texas and adolescents in Louisiana where potentially inadequate intakes were noted in the below poverty groups. On the other hand, among the elderly in Louisiana and Kentucky and infants in Michigan, the individuals living below poverty had smaller percentages of inadequate intakes than the group living above poverty.

The data suggest little relationship between poverty and adequacy of protein intake.

There appears to be a consistent relationship between dietary iron intake and socio-economic status in all age groups and in all areas. Those individuals living below poverty had greater percentages of inadequate intake than those living above poverty. These data are consistent with previously presented data (Tables 8A and 8B and Figures 1a and 1b), showing a greater relationship between hemoglobin levels and poverty than with the other biochemical measurements and poverty.

The data for vitamin A intake show slight variations between the above and below poverty groups. Trends in a number of groups, such as infants and adolescents, suggest a less adequate intake in the below poverty group.

In all areas studied, the below poverty group had a greater percentage of individuals meeting the standard for adequacy of vitamin C intake than among the above poverty groups. In general these data suggest that there is no major problem with vitamin C intake and support the previous suggestion, based on serum vitamin C data.

The only consistent trends noted in the data as a whole were in infants and adolescents where consistently high percentages of individuals fell below 70 percent of adequacy in regard to iron intake.

PARTICIPATION IN FOOD PROGRAMS

At the time of data collection, only a limited number of counties studied had either commodity foods or food stamps available. Thus the numbers reflected in Table 13F are misleading. The availability of both programs has increased substantially since these data were collected.

The data presented in Table 13F relative to school lunch participation are indicative that not only do substantial numbers of school children attend school where no lunch programs are available, but even when programs are available, participation is limited. These data appear to warrant further investigation into reasons for non-participation.
